

PROCESS FOR PRODUCING OXIDE FILMSBackground of the InventionField of the Invention

[0001] The invention generally relates to bismuth-containing oxide films. In particular, the present invention relates to a process for manufacturing bismuth-containing oxide thin films by Atomic Layer Deposition (ALD).

Description of the Related Art

[0002] Bismuth is a component of several technologically important binary and multicomponent oxide thin film materials, particularly the ferroelectric oxides $\text{Bi}_4\text{Ti}_3\text{O}_{12}$, $(\text{Bi},\text{La})_4\text{Ti}_3\text{O}_{12}$, and $\text{SrBi}_2\text{Ta}_2\text{O}_9$ and, also, the superconducting oxide $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$. Ferroelectric bismuth oxide films have great potential use in ferroelectric memory cells. In such uses, the films are likely to be formed with capacitors in the form of 3-D structures, which means that good conformality of the ferroelectric film is desired to ensure proper function of the memory cell.

[0003] Atomic Layer Deposition, in the following also abbreviated “ALD”, is a deposition method in which a product, such as a thin film, is deposited on a substrate from precursors in the vapor phase. ALD is based on sequential self-saturated surface reactions. The characteristics of an ALD process are described in detail in U.S. Patents Nos. 4,058,430 and 5,711,811 which are incorporated herein. The reactors designed for ALD benefit from the usage of inert carrier and purging gases, which makes the system faster.

[0004] According to the principles of the ALD, the source chemicals (or “precursors”) are separated from each other by inert gases (i.e., by purging) which substantially prevents gas-phase reactions between gaseous reactants, thereby facilitating the film growth by the above-mentioned self-saturated surface reactions. Advantageously, ALD requires neither strict temperature control of the substrates nor precise dosage control of source chemicals. Surplus chemicals and reaction by-products are removed from the reaction chamber before the next reactive chemical pulse is introduced into the chamber. Undesired gaseous molecules are effectively expelled from the reaction chamber by keeping the gas

flow speeds high with the help of an inert purging gas. The purging gas pushes the extra molecules towards the vacuum pump used for maintaining a suitable pressure in the reaction chamber. Advantageously, ALD provides an excellent and automatic self-control for the film growth as well as outstanding conformality.

[0005] Based on its general properties, ALD is a potentially attractive alternative for deposition of bismuth-containing oxide thin films. However, prior art attempts at the deposition of bismuth containing oxides by ALD had a number of shortcomings. The main problem has been finding appropriate bismuth - oxygen source combinations for depositing bismuth oxide. In an earlier article [M. Schuisky et al., Chem. Vap. Deposition 6 (2000) 139], triphenyl bismuth, a commonly used CVD precursor, was examined for depositing $\text{Bi}_4\text{Ti}_3\text{O}_{12}$. No binary Bi_2O_3 could be deposited, but bismuth could be incorporated into Bi-Ti-O mixture films. However, the levels were too low for forming the desired $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ phase. Application of BiCl_3 and water, in turn, has resulted in a BiOCl phase (M. Schuisky et al.). Trimethyl bismuth is another common bismuth (Bi) CVD precursor, but it is reported to be explosive. Quite recently, $\text{Bi}(\text{OCMe}_2\text{CH}_2\text{OMe})_3$ was introduced as a new Bi CVD precursor [P. A. Williams, Chem. Vap. Deposition 7 (2001) 205]. The present inventors tested this compound in ALD and found that it decomposes too easily when heated inside the reactor. Other tested compounds include $\text{Bi}(\text{CH}_2\text{SiMe}_3)_3$, for which no film growth has been observed with water as an oxygen source, and $\text{Bi}(\text{thd})_3$, which appears to be quite unstable based on TG measurements.

[0006] In their paper, Roy Gordon et al. (Chem. Mater. 13 (2001) 2463) reported the use of La silylamide for deposition of the corresponding oxide and a mixture of said compound with silicon oxide. The article further contains— it would appear — an exhaustive list of elements forming volatile silylamides. The article is, however, silent about the use of bismuth-containing silylamides.

[0007] As the above surveys show, there are no satisfactory processes known for producing bismuth-containing ferroelectric films by the Atomic Layer Deposition technique.

Summary of the Invention

[0008] It is an object of preferred embodiments of the invention to reduce the problems of the prior art and to provide a novel ALD process for producing bismuth-containing oxide thin films.

[0009] It is another object of preferred embodiments of the invention to provide binary and multicomponent oxide thin films containing bismuth and other metals for use as ferroelectric and dielectric materials and/or in superconductor applications.

[0010] These and other objects, together with the advantages thereof over known processes and products, are achieved by preferred embodiments of the present invention as hereinafter described and claimed.

[0011] According to a preferred embodiment of the present invention, it has been found that a specific group of organic bismuth compounds can be used as precursors for producing bismuth-containing oxide thin films (binary as well as multicomponent oxides of bismuth). The organic bismuth compounds of the preferred embodiments have in common that they all contain substituted silylamide ligands. The finding was surprising because silylamides are not known for being particularly stable compounds, and – as mentioned above in connection with the article by Roy Gordon *et al.* – there are no indications in the art of their applicability in ALD.

[0012] A preferred embodiment of the invention comprises a novel process for producing bismuth-containing oxide thin films, in which organic bismuth compounds having at least one bis(trialkylsilyl)amido ligand are used as precursors for depositing films by Atomic Layer Deposition. In such a preferred process, vapor phase pulses of

- an organic bismuth compound having at least one bis(trialkylsilyl)amido ligand as a source material of bismuth oxide and
- at least one oxygen source material capable of forming an oxide with the source material,

are alternately fed into a reaction space containing a suitable substrate in order to deposit bismuth-containing oxide thin films.

[0013] By introducing into the reaction space vapor phase pulses of a second source material, containing at least one transition metal or main group metal, followed by

suitable pulses of an oxygen source material, it is possible to produce ternary and other multicomponent bismuth oxide films.

[0014] According to one aspect of the invention, a process for producing a bismuth-containing oxide thin film by Atomic Layer Deposition (ALD) is provided. In this ALD process an organic bismuth compound having at least one silylamido ligand is used as a source material for the bismuth-containing oxide thin film.

[0015] According to another aspect of the invention, a process for depositing a bismuth oxide layer on a substrate by Atomic Layer Deposition (ALD) is provided. A vapor phase pulse of an organic bismuth compound source material having at least one bis(trialkylsilyl)amido ligand is fed into a reaction space. A pulse of an oxygen source material capable of forming an oxide with the organic bismuth compound source material is then pulsing into the reaction space. In certain embodiments, this process includes pulsing a second metal source into the reaction space to form a multi-component film, such as a ternary film.

[0016] Considerable advantages are obtained by the preferred embodiments. Thus, the novel ALD source materials, exemplified by tris(bis(trialkylsilyl)amido) bismuth(III), have been tested and found to work well as precursors for both binary and multicomponent oxides of bismuth. The properties of this novel precursor group are illustrated below by tris(bis(trimethylsilyl)-amido) bismuth(III) [in the following abbreviated Bi(btsa)₃]. Bi(btsa)₃ is a volatile compound, which is stable at a temperature range compatible with ranges used for the ALD deposition using precursors of many other metal components in bismuth-containing multi-component oxide materials. Therefore, the preferred embodiments make it possible to deposit thin films by ALD, while operating the process at conditions under which Bi(btsa)₃ is stable.

[0017] Films deposited by a preferred embodiment exhibit good thin films properties, e.g., they have excellent conformality even on uneven surfaces. As a result, the novel films can be used in 3-D folding and/or roughened capacitors. The invention also provides for excellent and automatic self-control of film growth.

[0018] Bismuth-containing oxide thin films produced by the preferred embodiments can be used, for example, as ferroelectric or dielectric material in integrated circuits and/or superconductor materials.

[0019] For purposes of summarizing the invention and the advantages achieved over the prior art, certain objects and advantages of the invention have been described herein above. Of course, it is to be understood that not necessarily all such objects or advantages may be achieved in accordance with any particular embodiment of the invention. Thus, for example, those skilled in the art will recognize that the invention may be embodied or carried out in a manner that achieves or optimizes one advantage or group of advantages as taught herein without necessarily achieving other objects or advantages as may be taught or suggested herein.

[0020] All of these embodiments are intended to be within the scope of the invention herein disclosed. These and other embodiments of the present invention will become readily apparent to those skilled in the art from the following detailed description of the preferred embodiments having reference to the attached figures, the invention not being limited to any particular preferred embodiment(s) disclosed.

[0021] Next, the preferred embodiments are described in detail with the aid of the following detailed description and by reference to the attached drawings.

Brief Description of the Drawings

[0022] Figure 1 shows graphically the experimental results obtained in the working example below of the saturation of the Bi-O growth rate from Bi(btsa)₃ and water at 200°C.

[0023] Figure 2 shows graphically the effect on the Bi/Ta ratio of a SrBi₂Ta₂O₉ film obtained by changing the cycle ratio and effect of layer thicknesses at a 1:1 cycle ratio.

[0024] Figure 3 shows an XRD diagram of an ALD SrBi₂Ta₂O₉ film annealed in air at 750°C.

[0025] Figure 4 shows an XRD diagram of an ALD Bi-Ti-O film annealed in air at 750°C.

Detailed Description of the Preferred Embodiment

[0026] In context of the preferred embodiments, “an ALD type process” generally refers to a process for producing thin films over a substrate in which a solid thin film is formed molecular layer by molecular layer due to self-saturating chemical reactions on heated surfaces. In the ALD process, gaseous vapor phase reactants, are conducted into a reaction chamber of an ALD reactor and contacted with a substrate located in the chamber to provide a surface reaction. The pressure and the temperature of the reaction chamber are adjusted to a range where physisorption (i.e., condensation) and thermal decomposition of the reactants are avoided. Consequently, only up to one monolayer (i.e., an atomic layer or a molecular layer) of material is deposited at a time during each pulsing cycle. The actual growth rate of the thin film, which is typically presented as Å/pulsing cycle, depends, for example, on the number of available reactive surface sites on the surface and bulkiness of the chemisorbing molecules. Gas phase reactions between precursors and any undesired reactions of by-products are inhibited because material pulses are separated from each other by time and the reaction chamber is purged with an inactive gas (e.g., nitrogen or argon) between material pulses to remove surplus gaseous vapor phase reactants and reaction by-products from the chamber. The principles of ALD type processes have been presented by Dr T. Suntola, e.g., in the Handbook of Crystal Growth 3, Thin Films and Epitaxy, Part B: Growth Mechanisms and Dynamics, Chapter 14, Atomic Layer Epitaxy, pp. 601-663, Elsevier Science B.V. 1994, the disclosure of which is incorporated herein by reference.

[0027] Extensive selection of ALD precursors and ALD-grown materials have been presented by Prof. M. Ritala and Prof. M. Leskelä in a recent review article, Handbook of Thin Film Materials, Vol. 1: Deposition and Processing of Thin Films, Chapter 2 “Atomic Layer Deposition”, pp. 103-159, Academic Press 2002.

[0028] In context of the present application “a reaction space” generally designates a reactor or a reaction chamber in which the conditions can be adjusted so that deposition of a thin film is possible.

[0029] In context of the present application, “an ALD type reactor” means a reactor where the reaction space is in fluid communication with an inactive gas source and at least one, preferably at least two precursor sources that can be pulsed, the reaction space is in

fluid communication with a vacuum generator (e.g., a vacuum pump), and the temperature and pressure of the reaction space and the flow rates of gases can be adjusted to a range that makes it possible to grow thin films by ALD type processes.

[0030] As known in the art, there are various variations of the basic ALD method, including PEALD (plasma enhanced ALD) in which plasma is used for activating reactants. Conventional ALD or thermal ALD refers to an ALD method where plasma is not used but where the substrate temperature is high enough for overcoming the energy barrier (activation energy) during collisions between the chemisorbed species on the surface and reactant molecules in the gas phase so that up to a molecular layer of thin film grows on the substrate surface during each ALD pulsing sequence. For the purpose of the preferred embodiments, ALD covers both PEALD and thermal ALD.

[0031] “Source material” and “precursor” are used interchangeably to designate a volatile or gaseous metal compound, which can be used as a starting compound for the corresponding metal oxide of the thin film. Reactants can include “precursors” (which leave a component on the film), but can also include, e.g., reducing agents.

[0032] The term “multicomponent oxide” covers oxide materials formed by at least two different metal cations.

[0033] According to certain preferred embodiments, bismuth precursors containing at least one, preferably 1 to 3, silylamido ligand(s) is/are used as source materials in production of thin films in ALD reactors. The precursors preferably contain three silylamido ligands. Such compounds are exemplified by tris(bis(trialkylsilyl)amido) bismuth(III), wherein the “alkyl” stands for a lower alkyl group, selected from methyl, ethyl, n- and i-propyl, and n-, sec- and t-butyl. In each ligand, and in different ligands, the alkyl groups may be same or different.

[0034] A specific example of the present novel precursors is tris(bis(trimethylsilyl)amido) bismuth(III) (Bi(btsa)₃) having the below formula:

Other suitable compounds are, for example, tris(bis(ethyldimethylsilyl)amido) bismuth(III), tris(bis(n-butyldimethylsilyl)amido) bismuth(III), tris(bis(triethylsilyl)amido) bismuth(III) and tris(bis(tri-n-propylsilyl)amido) bismuth(III). Although trialkylsilylamido compounds of bismuth are preferred as ALD reactants, versatile chemistry related to silylamido molecule makes it possible to replace one or more alkyl groups in the trialkylsilylamido molecule with other substitutions. Thus, in general, the ligand has a formula according to Equation 1:

in which each R¹, R², R³ is independently selected from

- linear or branched C₁-C₂₀ alkyl or alkenyl groups, preferably methyl, ethyl, n- and i-propyl, n-, sec- and t-butyl,
- halogenated alkyl or alkenyl groups, wherein at least one hydrogen atom is replaced with a fluorine, chlorine, bromine or iodine atom,
- carbocyclic groups such as aryl, preferably phenyl, alkylaryl, halogenated carbocyclic groups, and
- heterocyclic groups.

[0035] In addition to alkyl, ligands contain carbocyclic structures, such as aryls, e.g., phenyl groups (C₆H₅-), are preferred for use as silylamido compounds in ALD. Also,

halogenated silylamido compounds, including fluorinated trialkylsilylamido compounds, are considered advantageous ALD reactants. In such fluorinated compounds at least one hydrogen atom has been replaced with a fluorine atom.

[0036] Of the above mentioned precursors, the particularly preferred ones, namely the tris(bis(trialkylsilyl)amido) bismuth(III) compounds, are stable at least up to about 220°C and can generally be used in ALD processing at temperatures below about 250°C, typically below about 225°C, suitably at about 100°C to about 220°C, and preferably at about 150°C to about 200°C. According to the invention, gas phase pulses of the evaporated silylamido bismuth compound are introduced into an ALD reactor, in which they are contacted with a suitable substrate. The deposition can be carried out at normal pressure, but it is preferred to operate the method at reduced pressure. The pressure in the reactor is typically 0.01 – 20 mbar, preferably 0.1 – 5 mbar. The substrate temperature is preferably low enough to keep the bonds between thin film atoms intact and to prevent thermal decomposition of the gaseous reactants. On the other hand, the substrate temperature is preferably high enough to keep the source materials in gaseous phase, i.e., condensation of the gaseous reactants should be avoided. Further, the temperature (or the energy source) must be sufficiently high to provide the activation energy for the surface reaction. Optionally, an inactive gas is used as a carrier gas during deposition.

[0037] At these conditions, the amount of reactants bound to the surface will be determined by the reactive sites available at the surface. This phenomenon is called "self-saturation".

[0038] For further details on the operation of a typical ALD process, reference is made to the documents cited above.

[0039] The substrate can be of various types. Examples include silicon, silica, coated silicon, germanium, silicon-germanium alloys, copper metal, noble and platinum metals group including silver, gold, platinum, palladium, rhodium, iridium and ruthenium, various nitrides, such as transition metal nitrides (e.g., tantalum nitride TaN), various carbides, such as transition metal carbides (e.g., tungsten carbide WC), and nitride carbides (e.g., tungsten nitride carbide WN_xC_y). Conventionally, the preceding thin film layer deposited will form the substrate surface for the next thin film. For both ferroelectric

capacitor structures and superconductor applications, bismuth-containing films are generally deposited on appropriately patterned metal surfaces (electrodes).

[0040] In order to convert the adsorbed bismuth precursor into bismuth oxide, the reactor is purged with a purge gas such as an inactive gas, and then a next vapor phase pulse of an oxygen source material is introduced into the reactor. The oxygen source material is preferably selected from the group of water, oxygen, hydrogen peroxide, aqueous solution of hydrogen peroxide, ozone, oxides of nitrogen, halide-oxygen compounds, peracids ($--O--O--H$), alcohols, alkoxides, oxygen-containing radicals and mixtures thereof.

[0041] By alternating the reactions of the bismuth precursor and the oxygen source material, a bismuth-containing oxide thin film can be deposited. Typically, a growth rate of about 0.20 to 0.30 Å/cycle is achieved.

[0042] In order to produce multicomponent oxide films, a second metal source material can be introduced under ALD conditions. Such a precursor can be metal compound or a complex metal compound comprising two or several metals. The metals are typically selected from the group of volatile or gaseous compounds of transition metals and main group metals, i.e., elements of groups 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13 and/or 14 (according to the system recommended by IUPAC) in the periodic table of elements.

[0043] Since the properties of each metal compound vary, the suitability of each metal compound for the use in the process of the preferred embodiments should be considered. The properties of the compounds are found, e.g., in N. N. Greenwood and A. Earnshaw, Chemistry of the Elements, 1st edition, Pergamon Press, 1986.

[0044] Typically, suitable metal source materials can be found among halides, preferably fluorides, chlorides, bromides or iodides, or metal organic compounds, preferably alkoxy (See the titanium alkoxide of Example 4), alkylamino, cyclopentadienyl, dithiocarbamate or betadiketonate compounds of the desired metal(s). Also double metal precursors, i.e., molecules containing two metals in a discrete ratio, may be used (See Example 2 below).

[0045] In a preferred embodiment of the present invention, a multicomponent oxide film consists essentially of Bi, Ca, Sr, Cu, Ti, Ta, Zr, Hf, V, Nb, Cr, W, Mo, Al, Si and/or Pb oxide(s) and, thus, the corresponding gaseous or volatile compounds are preferably

used. The second metal source material can be oxidized using the same or another oxygen source material as for the bismuth precursor. For example, the multicomponent oxide film can be $\text{Bi}_4\text{Ti}_3\text{O}_{12}$, $(\text{Bi},\text{La})_4\text{Ti}_3\text{O}_{12}$, $\text{SrBi}_2\text{Ta}_2\text{O}_9$ or $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$

[0046] In certain preferred embodiments, aluminium and silicon are particularly interesting as sources of a second and/or third metal in ternary and other multicomponent bismuth-containing oxides. Multicomponent Bi/Al and/or Si oxides are potentially valuable as high-k dielectric material. In other preferred embodiments, the ternary oxide thin film consists of a second metal such as copper, titanium, tantalum, calcium, strontium, silicon, or aluminum.

[0047] According to one preferred embodiment, multicomponent films are produced by feeding alternating pulses of the various metal precursors (followed by the above mentioned oxygen source pulses) into an ALD reactor. This embodiment based on “mixing cycles” will give rise to a ferroelectric phase after deposition. Typically, the ratio of first cycles (consisting of bismuth-containing precursor followed by oxygen source pulses) to second cycles (consisting of a second metal source followed by the corresponding oxygen source pulses) is about 20:1 to about 1:20, preferably about 10:1 to 1:10, more preferably about 6:1 to about 1:3. A stoichiometric surplus of about 1 to 20 atomic percentage of bismuth in the films is advantageous for some applications, particularly including $\text{SrBi}_2\text{Ta}_2\text{O}_9$. An example of this embodiment is given in Example 2 below.

[0048] Another preferred embodiment comprises preparing multicomponent films by depositing laminar layers of each metal oxide and annealing the laminar layers together at increased temperatures to provide a ferroelectric phase. In this way, an amorphous structure is first provided and the ferroelectric phase can be obtained by annealing in the presence of oxygen (such as in the presence of air) at temperatures in excess of 500°C, in particular in excess of 700°C. The advantage of this embodiment is that the composition of the films can be controlled by adjusting the thickness of the laminar layers. This embodiment is illustrated in Example 3 below.

[0049] A third preferred embodiment for preparing binary films comprises a combination of the above described embodiments. Thus, the cycle mixing approach can be used for producing a mixed bismuth-titanium, bismuth-tantalum or bismuth-hafnium oxide

film. If the film is amorphous, it can be annealed at the temperatures mentioned above, in the presence of air or another oxygen-containing gas.

[0050] In the above embodiments, where a second and possibly further metal precursors are fed into an ALD reactor, a vapor phase pulse of an oxygen source material is preferably, but not necessarily, fed into the ALD reactor after each metal precursor pulse and optionally after the purge gas pulse following the metal precursor pulse.

[0051] The present novel thin film oxide materials will find extensive application in the semiconductor industry as ferroelectric materials for nonvolatile memories. The production of Bi-containing superconductor films is also of interest in the superconductor device industry.

[0052] The following non-limiting examples illustrate certain preferred embodiments of the invention. They were carried out in an F-120TM ALD reactor supplied by ASM Microchemistry Oy, Espoo.

[0053] Tris(bis(trimethylsilyl)amido) bismuth(III) was basically synthesized as described by Carmalt *et al.* [C. J. Carmalt, N. A. Compton, R. J. Errington, G. A. Fisher, I. Moenandar, N. C. Norman, *Inorganic Synthesis*, 1997, 31, 98-101]. Thus, BiCl₃ was reacted with Li(N(SiMe₃)₂) to yield the desired compound. However, the method of Carmalt *et al.* was modified by using pure THF as a solvent in the synthesis step instead of the solvents, Et₂O and mixture of Et₂O and THF, proposed in the article. Further, the reaction was also carried out at lower temperature (−12 °C vs. 0 °C) and, instead of pentane, hexane was used to dissolve the crude product before filtration. The final product was as described in the article and the yield was somewhat better.

[0054] The other reagents are commercially available.

Example 1

[0055] ALD Growth of Bi₂O₃ from Bi(btsa)₃ and H₂O was carried out at temperatures in the range of from 150 to 200°C. At deposition temperatures of 225°C and above, no significant growth was observed, probably due to precursor decomposition. At 200°C the Bi-O growth rate saturates at 0.23 Å/cycle (Figure 1).

Example 2

[0056] $\text{SrBi}_2\text{Ta}_2\text{O}_9$ films were deposited at 200°C by mixing $[\text{Bi}(\text{btsa})_3 - \text{H}_2\text{O}]$ and $[\text{SrTa}_2(\text{OEt})_{10}(\text{dmae})_2 - \text{H}_2\text{O}]$ cycles (Figure 2). Average growth rates were roughly 0.2 Å/cycle. At a 2:1 cycle mixing ratio, films were obtained having 8 atomic percentage Bi in excess of stoichiometric. This composition is suitable for ferroelectric applications.

Example 3

[0057] A second approach was also used for depositing $\text{SrBi}_2\text{Ta}_2\text{O}_9$. Thus, amorphous laminate layers of Sr-Ta-O and Bi-O were grown. In this case, the overall composition was adjusted by varying the thicknesses of these layers, and the desired compound was formed by reacting the layers with each other in the following annealing steps. All the as-deposited SBT films were amorphous, but after annealing in air at 750°C the desired ferroelectric phase was observed (Figure 3).

Example 4

[0058] Using the cycle mixing approach of Example 2 with $[\text{Bi}(\text{btsa})_3 - \text{H}_2\text{O}]$ and $[\text{Ti}(\text{OMe})_4 - \text{H}_2\text{O}]$ cycles, Bi-Ti-O films were grown at 200°C. $\text{Bi}_4\text{Ti}_3\text{O}_{12}$, a ferroelectric phase, was observed after annealing as-deposited films in air at 750°C (Figure 4).

[0059] Although this invention has been disclosed in the context of certain preferred embodiments and examples, it will be understood by those skilled in the art that the present invention extends beyond the specifically disclosed embodiments to other alternative embodiments and/or uses of the invention and obvious modifications thereof. Thus, it is intended that the scope of the present invention herein disclosed should not be limited by the particular disclosed embodiments described above, but should be determined only by a fair reading of the claims that follow.
